Abstract

**Background:** Dentigerous cyst (DC) is the second most common cyst of the jaw after radicular, affecting mostly the permanent dentition in the mandible (70%). DC Of maxillary sinus involving ectopic teeth is rare.

**Case details:** We report a case of DC of maxillary sinus as well as anterior mandible associated with ectopic teeth, in a non-syndromic 8 years old boy who underwent cyst enucleation along with extraction of the involved teeth.

**Conclusion:** DC affecting both maxilla and mandible is a less common entity. Treatment modality can range from enucleation to simple marsupilisation depending upon the extent of the lesion.

**Keywords:** Dentigerous Cyst; Maxillary Sinus; Enucleation; Ectopic Teeth

1. Introduction

Dentigerous cyst (DC), also termed as “follicular cyst” are the most common type of developmental odontogenic cyst associated with impacted, unerupted, or embedded teeth Prashad et al. 2007, Buyukkurt et al. 2010). Multiple DC generally occur in association with a developmental syndrome or systemic diseases. Abnormal tissue interaction during tooth development may potentially result in ectopic tooth development and eruption (Prashad et al. 2007, Buyukkurt et al. 2010). The pathogenesis of the cyst is unknown and are believed to originate from dental follicles. The epithelial-lined developmental cavity encloses the crown of an unerupted tooth at the cement-enamel junction (Ko et al. 1999). The expansion of dental follicles resulting from accumulation of fluid between reduced enamel epithelium and tooth enamel exerts pressure on the follicle which in turn obstructs the venous outflow leading to rapid transudation of serum across capillary walls increasing the hydrostatic pressure (Ziccardi et al. 1997). This separates the follicle from the crown, DC account for about 24% of all jaw cyst (Ko et al. 1999). Third molars, maxillary canines and premolars are the most frequently affected teeth. Maxillary teeth are often displaced into the maxillary sinus and hence, the sequelea may vary from sinus obstruction to even blindness (Litvin et al. 2008).

DC can be treated by either enucleation or marsupilisation. Enucleation of the cyst along with extraction of the associated unerupted teeth. However, enucleation is considered more aggressive whereas marsupilization comes with the disadvantage of recurrence or persistence of the lesion (Tournas et al. 2006, Buyukkurt et al. 2010.). In larger cyst initial marsupilization to diminish the osseous defect, followed by enucleation and extraction has been advocate (Ziccardi et al. 1997, Buyukkurt et al. 2010.). In this paper we report a case of DC in a 8 year old boy, associated with unerupted teeth in the maxillary sinus and anterior mandible.

2. Case report

A 8 year old boy visited our Out–Patient Department with a chief complaint of swelling over left side face for the last 2 months. On examination a swelling measuring approximately 4x3 cms was found on left side of the face extending from left infra-orbital rim upto the left corner of the mouth (Fig 4). Mediolaterally, the swelling extended from left ala of the nose, mildly elevating the nasobuccal crease, up to lateral canthus of left eye. Intraoral examination showed swelling over left alveolobuccal complex, obliterating the vestibule from left lateral maxillary incisor upto the tuberosity. Labio-palatal expansion was noted in the anterior arch of maxilla causing gross mobility of the erupting first and second bicuspids. Intraoral mandibular finding revealed mild degree of vestibule elevation in the region of left lateral incisor region, which was displaced. On palpation, the swellings were non-tender, semisolid and fluctuant.
Panoramic radiograph revealed a relatively large and well-defined radiolucency on the left side of maxilla as well as anterior mandible, both enveloping an unerupted tooth. The unerupted teeth were displaced anterosuperiorly in maxilla and inferiorly near the lower border in the mandible (Fig. 2). Computed Tomography scan showed a cystic lesion measuring 4.5 cms horizontally, 4 cms vertically and 3 cms antero-posteriorly with expansion and erosion of maxillary sinus cortical bone. (Fig. 3 and 4). The mass was seen to extend into left lateral nasal wall displacing the osteo-meatial complex towards the opposite side and causing mild elevation of the orbital floor. Posterioly the mass was seen extending upto left pterygomaxillary fissure (Fig. 3 and 4). The cyst in the mandible showed mild intra-bony expansion measuring 4cms x 2 cms x 1cms along with erosion of buccal cortical plate in the anterior mandible without involving the lingual cortex. The tooth con-
tained in the cyst was displaced inferiorly towards the lower border.

After haematological analysis the patient underwent enucleation of the cysts with extraction of the impacted teeth under General Anesthesia. Caldwell -Luc approach was employed to access the cyst in the maxillary sinus .The cystic lining was identified after breaching into the thinned antero and posterolateral wall and was separated from the sinus walls underneath. A maxillary impacted canine was found near the anteromedial wall. Careful dissection lead to removal of whole of the cystic lining in-toto along with the impacted canine (Fig.5). Vestibular incision was used to enucleate the mandibular cyst in-toto along with the embedded tooth. La-

belled samples from maxilla and mandible in two different speci-
cans were sent for histopathology examination.

Histopathological examination revealed a lining of stratified squamous epithelium and granulation tissue with chronic inflam-

matory infiltrate in the underlying connective tissue. Occasional mature keratinizing squamous cell nests was noted in the colla-
genous cystic wall (Fig.6). A diagnosis of dentigerous cyst was made for both the samples.

3. Discussion

Dentigerous cysts are the most common type of developmental odontogenic cyst and are the second most common cystic lesion of the jaw, after radicular cyst (Tournas et al. 2006, Buyukkurt et al. 2010). About 70% of the cyst occur in posterior mandible and 30 % in maxilla. It usually involves the third molars .In our case, the cyst was found in the mandible as well as the maxilla involving the unerupted cuspids. Moreover, the cyst in the mandible was found in the anterior region ,in contrast to its most common loca-
tion.

DC are usually present in the second or third decade of life and rarely seen in childhood (O’Neil et al. 1989, Ustunner et al. 2003). Few authors suggest its prevelance among the younger patients below 20 yrs old (Takagi & Koyoma 1999, Ertas & Selim 2003.). However, age range of 4 yrs to 57 yrs are reported . In our case it was seen to be affecting a eight yrs old boy.

DC are known be to asymptomatic which gradually grows over time and are generally presented only when it attains sizes big enough to cause gross intraoral swelling or teeth displacements and facial asymmetries while others are found incidentally during routine radiographic examinations (Tournas et al. 2006). In our case, the patient presented to us with swelling over his left side of face with a duration of just one month while he had no clini-

cal presentation of the cyst in the mandible, which was discovered in radiographs that were only intended to be taken for the maxil-

lary cyst. Cyst involving the maxillary sinus may be presented with symptoms like swelling, pain, headache, and nasolacrimal obstruction (Takagi & Koyoma 1999 , Tournas et al. 2006). Ophthal-

mic symptoms like epiphora, proptosis, diplopia (Golden et al. 1981, Atlas et al. 1997) and even blindness have been reported (Savundranayagam 1972). Numbness or parasthesia due to nerve compression can also occur (Takagi & Koyoma 1999).

Water view, OPG, plain skull radiographs are simple and inexpen-
sive radiographs that can be utilized to detect cystic lesions of jaws. Panoramic views are favoured over CT by some as to detect the structures of teeth. However, CT scans are requisite in defining the extension of masses extending into surrounding vital structures like the nasal or orbital cavity. Also they provide superior detail on bony involvement, associated pathology, exact location of ec-
topic tooth all of which help in definite diagnosis and treatment planning (Atlas et al. 1997).

Differential diagnosis of DC includes radicular cyst, odontogenic cyst, odontogenic keratocyst, odontogenic tumours like ameloblas-
toma, Pindborg tumour, odontoma. However, mucoceles, retention cyst and pseudocyst can be included in the differential diagnosis in case of maxillary cyst (Ustunner et al. 2003, Tournas et al. 2006). Odontogenic tumours like ameloblastoma or epidermoid carcinomas are reported to be risen from lining of DC (Ustunner et al. 2003, Tournas et al. 2006). No metaplastic and dysplastic changes arising from DC of maxillary sinus are reported in the literature. The Standard Treatment for DC is enucleation and extraction of the cyst-associated impacted or unerupted teeth (Tournas et al. 2006, Buyukkurt et al. 2010 9). However, marsupilization are advisable in larger cyst and thought to be more efficient in chil-
dren (Ko el al. 1999, Takagi & Koyoma 1999) as it conserves the affected tooth and facilitates its eruption. However, certain factors are requisite to determine the eruption potential of the involved tooth. Some studies shows that if the axis of inclination of the tooth less than 80° of tooth axis angulation or less than 9 mm depth in bone are predictive of eruption(Hyomoto et al. 2003). In our case, the teeth involved were extracted along with complete cystic enucleation. The patient is being followed-up for the past 2 months with no evidence of recurrence till date.
