Abstract

Background: Fluoride is an inorganic element present everywhere in the environment and has cumulative toxic effects from prolonged ingestion. Green tea used since ancient times as a medical drink due to its multiple health benefits owing to its anti-oxidative and anti-apoptotic activities. Aim: To the best of our knowledge there were no studies until now concerning the possible protective role of green tea extract on the intestinal mucosal changes induced by fluoride on adult albino rats, so this work tried to investigate this role. Materials and Methods: Forty male adult albino rats randomly and equally divided into four groups, Group I: received distilled water only orally via a gastric tube. Group II: received green tea extract (GTE) 150 mg/kg dissolved in distilled water and freshly prepared for 35 days. Group III: received sodium fluoride (NaF) once daily oral dose of 10 mg/kg dissolved in distilled water for 35 days. Group IV: received NaF in the same dose as group III concomitant with GTE as the previously adjusted dose for 35 days. Body weight of all the studied groups was recorded at the start and after 35 days from the beginning of this study. After that the study tested the antioxidant and oxidant parameters in intestinal tissue as MDA, reduced GSH, and CAT, histopathological and immunohistochemical examination of intestinal tissue using PCNA marker were also included. Results: the rate of weight gain was little in NaF group compared to other group. Concomitant administration of GTE with NaF resulted in highly significant decrease in MDA level, highly significant increase in reduced GSH level and highly significant elevation in CAT level when compared with NaF group. Many of abnormalities as moderate increase in goblet cell mass and highly expression of PCNA stain in a form of brown nuclear coloration were detected in intestinal tissues in NaF group by histopathological and immunohistochemical study that improved with administration of GTE. Conclusion: concomitant administration of GTE was improved the biochemical, histopathological and immunohistochemical alterations in intestinal mucosa that treated with NaF.

Keywords: Antioxidant; Fluoride; Green Tea Extract; Intestinal Mucosa.

1. Introduction

Fluoride is an inorganic anion element present everywhere in the environment and has a highly prophylactic effect at low concentrations by preventing dental caries, while at high concentrations it causes harmful effects as dental and skeletal fluorosis (Chachra et al., 2008; Ozsvath, 2009).

Fluoride also has cumulative toxic effects from prolonged ingestion that lead to fluorosis which is a condition persistent especially in third world where people have little choice of the main source of drinking water that is often contaminated with fluoride, water supplies, dietary ingredients, dental products, industrial emissions and occupational exposure which is higher than the safe dose (Ozsvath, 2009). Fluoride crosses the cell membrane very rapidly and distributed from the plasma to all tissue and organs (Bouaziz et al., 2006). Fluoride in high concentration also founded to affect memory function in some experimental animals and causing dysfunctions of the central nervous system and decrease learning ability. Epidemiological studies reveal that intelligence quotient of children living in endemic fluorosis places are lower than that of children living in low fluoride places (Xiang et al., 2003; Wang et al., 2007; Ozsvath, 2009).

In general tea is the most popular beverage, after water, drunken by more than 2/3 of the world’s population. It is rich in substances with antioxidant properties and has little proteins, amino acids, lipids and some vitamins and minerals (Gupta et al., 2002). The tea leaves are characterized by their content of methylxanthenes and polyphenols especially flavonols of the catechin type (Finkel and Holbrook, 2000; Perwez et al., 2003; Barnham et al., 2004).

Green Tea consumption has linked to regress various forms of diseases as cancer, diabetes, depression, cardiovascular and neurological disorders due to its antioxidative, antiapoptotic activities (Khan and Mukhtar, 2007; Ramesh et al., 2017).
Green tea polyphenols found to inhibit growth of stomach cancer and gastritis and regulate intestinal functions (Shimizu, 1999). Green tea catechins also found to protect GIT mucosa and prevent intestinal atrophy (Asfar et al., 2003). Green tea catechins improve gut flora by increase the growth of the bacteria in the gut wall and decrease the levels of violent pathogens (Goto et al., 1998). To the best of our knowledge, there are no studies concerning the toxic effects of chronic exposure to sodium fluoride (NaF) on the intestine of albino rats and the impact of synchronous administration of green tea extract as antioxidant therapy, therefore, this study tried to evaluate the possible protective role of green tea extract on the intestinal mucosal changes induced by fluoride on adult male albino rats.

2. Materials and methods

2.1. Drugs and chemicals

1) Green tea extract (GTE) was purchased from Technomed Groups Company, Egypt, "in the form of tablets (200 mg)". The tablets were dissolved in distilled water.

2) Sodium Fluoride (NaF) was obtained from El-Gomhoria Co. for Chemical Products, Al-Amyeria, Cairo, Egypt as NaF powder which is white water-soluble powder.

3) Nuclear Antigen (PCNA): PCNA monoclonal antibody (clone pc 10) was purchased from Lab Vision USA by Medico Trade Company, Giza, Egypt.

4) All kits used for different oxidative/antioxidative markers (malondialdehyde MDA; glutathione GSH; and catalase CAT) were purchased from Laboratory BioDiagnostics Co.,Giza, Egypt.

2.2. Animals

Forty male adult albino rats weighing 200-250 g were obtained from Experimental Animal Breeding Farm, (Helwan-Cairo). They were caged 10 per cage in well-ventilated place at room temperature in the animal house at the Department of pharmacology, Benha Faculty of Medicine for 2 weeks of acclimatization. They allowed free water and standard food (pellets specific for rat feeding obtained from animal breeding farm) on a schedule of 12 hours of light and 12 hours of dark. The time of dose administration was fixed for all animals at 12 P.M. During the whole period of experiment, animals were treated humanely according to the protocol of handling of experimental animals of Benha Faculty of Medicine.

2.3. Study design

Forty adult male rats randomly divided into four groups, each consisted of 10 animals, and distributed as follows:

Group I: Rats received distilled water only orally via a gastric tube.

Group II: Rats received green tea extract (GTE) 150 mg/kg body weight dissolved in distilled water and freshly prepared for 35 days (Hamdy et al., 2012).

Group III: Rats received sodium fluoride (NaF) once daily oral dose of 10 mg/kg body weight dissolved in distilled water and freshly prepared. Each gram of NaF was dissolved in 100 ml of distilled water to obtain a solution of concentration of 10 mg NaF/ml water for 35 days (Błaszczyk et al., 2008).

Group IV: Rats received sodium fluoride (NaF) in the same dose as group III concomitant with GTE as the previously adjusted dose for 35 days.

2.4. Procedural details

2.4.1. Body weight

Body weight of control, GTE, NaF and (GTE+NaF) treated rats were recorded at the start of the study and after 35 days from the beginning of this study.

After 35 days from the beginning of experiment, both control and the studied groups were sacrificed by inhalation of high dose of ether and the abdomen was explored; the intestine specimens were rapidly removed and subjected to the following techniques:

2.4.2. Tissue oxidative stress parameters

1) MDA assay: Intestinal tissue samples were irrigated with a solution of sodium chloride 0.9% and with potassium chloride 1.5%, homogenization at a ratio of 1:10 was achieved. The lipid peroxide level in the centrifuged tissue homogenates was measured according to the method described by Ohkawa et al. (1979). The reaction product was assayed spectrophotometrically at 532 nm. The lipid peroxide level was expressed as the nmol of MDA/ mg of intestinal tissue protein. Protein levels were measured according to the method described by Lowry et al. (1951).

2) Reduced GSH: reduced GSH content was determined with dithionitrobenzoic acid using the method described by (Beutler et al., 1963) and was expressed in μmol GSH/mg protein. The method is based on the reduction of DTNB to produce a yellow compound. The reduced chromogen is directly proportional to GSH concentration and its absorbance can be measured at 412 nm.

3) Catalase: The catalase (CAT) activity was measured by monitoring H2O2 decomposition at 240 nm according to the method described by Aebi (Aebi, 1984).

2.4.3. Histopathological study

Immediately after scarifications of animals and dissection, intestine from different groups were quickly removed, washed in 0.9 saline solutions and samples of intestine were fixed in 10 % neutral buffered formalin. After fixation, specimens were dehydrated in an ascending series of alcohol, cleared in two changes of xylene and embedded in molten paraffin (mp. 50–58°C). Sections of 7 microns thickness were cut using rotary microtome and mounted on clean slides. Sections were stained with Ehrlich's haematoxylin and counterstained with eosin as a routine method of Bancroft and Stevens (Bancroft and Stevens, 1990).
2.4.4. Immunohistochemical study using proliferating cell nuclear antigen (PCNA)

Paraffin blocks were prepared from intestines already fixed in 10% formalin for two days. Paraffin sections were stained with avidin–biotin peroxidase technique for proliferating cell nuclear antigen (PCNA) using the method described by (Bancroft and Stevens, 1996; Hall et al., 1990).

2.5. Statistical analysis

The collected data were tabulated and analyzed using SPSS (Statistical package for social science) version 20. Data were presented as mean and standard deviation for quantitative data, frequency, and distribution for qualitative data. They were tested using ANOVA test (F value) used to compare mean of more than two groups of quantitative data with using post hoc test (LSD) for inter-group comparison, corrected chi-square test used for Inter-group comparison of categorical data. The accepted level of significance in this work was started at 0.05 (Greenberg et al., 1996).

3. Results

3.1. Body weight measurements

Body weights of all groups were recorded at the beginning of the study and after 35 days of the treatment. Table (1) shows the mean of the initial and final body weights (g). On average, the rats of all groups gained weight throughout the experimental period, when compared to the initial body weight. At the beginning of the study, mean initial body weight showed non-significant difference between the studied groups (p > 0.05) while at the end of the study (after 35th day) the final body weight was significantly (p<0.05) higher in all groups compared to initial body weight with high significant (p < 0.001) increase in final body weight in control and GTE groups compared to NaF group with significantly (P < 0.05) increase in final body weight in (NaF+GTE) group versus NaF group and non-significantly increase in final body weight in control versus GTE group.

3.2. Tissue oxidative stress parameters

As regarding mean Malondialdehyde (MDA) level, there was a considerable decrease in MDA level in GTE group when compared to the control group, while NaF administration resulted in highly significant increase in MDA level when compared to both the control and GTE group. Concomitant administration of GTE with NaF in the (NaF+GTE) group resulted in great improvement representing in a highly significant decrease in MDA level as compared with NaF group (Table 2).

Regarding mean reduced GSH level, there was a highly significant rise in reduced GSH level in GTE treated rats as compared to control group; NaF administration resulted in highly significant decrease in reduced GSH level as compared to control and GTE group. Concomitant administration of GTE with NaF leads to highly significant increase in reduced GSH level when compared with NaF group but still highly significant lower than the control and GTE groups (Table 3).

Regarding mean catalase (CAT) level, there was a highly significant rise in CAT level in GTE treated rats as compared to control group; NaF administration resulted in highly significant decrease in CAT level as compared to control and GTE group. Concomitant administration of GTE with NaF leads to highly significant elevation in CAT level when compared with NaF group but still highly significant lower than the control and GTE groups (Table 4).

3.3. Histopathological changes of the intestinal mucosa of the studied groups

The changes in the intestinal mucosa of the studied groups were detected by histopathological examination using Hematoxylin and Eosin stain. Examination of Hematoxylin and Eosin stained sections of intestinal mucosa in group I show normal structure of intestine (crypts of Lieberkuhn) and goblet cells are the most cells lining the crypts (Fig.1). Group II shows some crypts with crowded villi and dilated lumens mainly in their basal parts (Fig. 2) while group III shows moderate increase in goblet cell mass (Fig. 3) and group IV showed mild increases in goblet cell mass (Fig. 4).

3.4. Immunohistochemical results

Changes in the intestinal mucosa of the studied groups were examined immunohistochemically by Proliferating Cell Nuclear Antigen (PCNA) marker to detect proliferating changes that occur in the nucleus. PCNA known as a regulated nuclear protein for DNA polymerase and the PCNA-labeled nuclei identify the cells in the late G1 and early S phases of the cell cycle and the cells subjected to DNA repair. PCNA expression was used as an index for these changes by counting the average number of the stained nucleus that attained brown coloration (Fig. 6). Group I showed low expression of PCNA in the nucleus (crypts of Lieberkuhn) and goblet cells are the most cells lining the crypts (Fig.1). Group II shows some crypts with crowded villi and dilated lumens mainly in their basal parts (Fig. 2) while group III shows moderate increase in goblet cell mass (Fig. 3) and group IV showed mild increases in goblet cell mass (Fig. 4).

4. Discussion

In the current study, after 35th day, the final body weight was significantly increased in all groups compared to initial body weight with high significant increase in final body weight in control and GTE groups compared to NaF group. Also, there was significant increase in final body weight in (NaF+GTE) group versus NaF group and non-significant increase in final body weight in control versus GTE group. These data are in line with Basha and Sujitha (2011) who observed decreased food and water intake and the rate of weight gain was little in rats administrated high fluoride dose in their diet. Also, Shankar et al. (2012) mentioned the that the rate of weight gain was little with decrease in fluoride excretion and increased bone fluoride deposition in animals administrated fluoride in their diet and reported that chronic fluoride intoxication may interfere with calcium absorption by decreasing S100G expression. The rate of weight gain was little in NaF group may be due to decreased in appetite leading to decreased consumption of food and water, which lead to decrease in growth. Furthermore, it may be due to primary malnutrition caused by fluoride which displaced other nutrients in the diet and cause secondary malnutrition results from maldigestion or malabsorption of nutrients. In addition, gastrointestinal complications may also change nutritional absorption (Abdel Salam et al., 2013).

Regarding mean Malondialdehyde (MDA) level, the result of the present work reveled that there was a considerable decrease in MDA level in GTE group when compared to the control group, while NaF administration resulted in highly significant increase in MDA level when compared to both the control and GTE group. Concomitant administration of GTE with NaF in the (NaF GTE) group resulted in great improvement representing in a highly significant decrease in MDA level as compared with NaF group. This result in agreement with the study of Shivarajashankara et al. (2003) that reported that oxidative stress increased in fluoride toxicity which causes increase in malondialdehyde (MDA) levels in red blood cells. Also, in a study done by El-Banna et al. (2019) revealed that concurrent administration of GTE with nicotine can decrease the oxidative stress as green tea polyphenols considered a powerful antioxidant.

Regarding mean reduced GSH level, the result of the present work reveled that there was a highly significant rise in reduced GSH level in GTE treated rats as compared to control group; NaF administration resulted in highly significant decrease in reduce GSH level as compared to control and GTE group. Concomitant administration of GTE with NaF leads to highly significant increase in reduce GSH level when compared with NaF group but still highly significantly lower than the control and GTE groups. This result is in line with Shivarajashankara et al. (2003) that reported increased levels of total and reduced glutathione in RBCs in fluoride toxicity. Previous studies showed that fluoride increases the liberation of oxygen free radicals and decreases the activity of substances as catalase, superoxide dismutase, and glutathione peroxidase, which have a potent role in antioxidation and removal of free radicals (Yu et al., 2006).

Regarding mean catalase (CAT) level, the result of the present work reveled that there was a highly significant rise in CAT level in GTE treated rats as compared to control group; NaF administration resulted in highly significant decrease in CAT level as compared to control and GTE group. Concomitant administration of GTE with NaF leads to highly significant elevation in CAT level when compared with NaF group but still highly significantly lower than the control and GTE groups. This result is in line with the study of Sara et al. (2018) which reported that cisplatin caused decrease in catalase activity in the intestine that increased by green tea administration. Gurney et al. (2007) reported that the decreased CAT level in uterine tissue in rats treated with fluoride due to increased oxidative stress as a result of hydrogen peroxide. Also, Shanthakumari et al. (2004) reported increase in level of lipid peroxides and decrease in the activities of SOD, catalase, glutathione peroxidase and reduced glutathione in fluoride group of rats. A lot of studies have reported that fluoride led to oxidative stress, lipid peroxidation, and reduced antioxidant enzyme activities in vivo or in vitro (Shanthakumari et al., 2004; Shan et al., 2004). Administration of tea polyphenols can improve decreases in antioxidant enzyme activities.
activities in animal. Administration of green tea polyphenols in the drinking water of mice significantly improved epidemical catabase and glutathione reductase activities (Agarwal et al., 1993).

PCNA known as regulated nuclear protein for DNA-polymerase and the PCNA-labeled nuclei identify the cells in the late G1 and early S phases of the cell cycle and the cells subjected to DNA repair (Itoh et al. 2000; Chen et al. 2005).

In the present work, the immunohistochemical results using PCNA showed that administration of NaF led to highly increase in expression of PCNA and apoptosis in intestinal mucosal cells, however, the administration of green tea extract led to decrease the protein expression of PCNA and apoptosis in these cells.

Anuradha et al. (2001) reported that NaF may causes apoptosis through lipid peroxidation resulted from oxidative stress leading to release of cytochrome C in the cytosol and trigger the caspase causing apoptotic cell death. Furthermore, there is a relationship between DNA damage, apoptosis and lipid peroxidation caused by fluoride (Wang et al., 2004).

Sara et al. (2018) founded that cisplatin caused significant changes in intestinal mucosal membrane and green tea administration caused improvement of these changes due to its antioxidant activities.

Liu et al (2003) reported that the mechanism of fluoride toxicity may be that fluoride causes increase in production of nitric oxide, lipid peroxides or oxygen free radicals that lead to reduced ability to remove the free radicals and decrease the antioxidation which strongly lead to injury to the structure specially the biological membrane, proteins , nuclei acids , the soft tissues and affect the cells functions. Matsui et al. (2007) founded that NaF increased intracellular Ca2+ concentration and significantly increased the number of shrunken cells which are the early stage of apoptosis and reported that NaF causes necrosis with some apoptotic alterations. Stawiarska-Pięta et al. (2012) also reported that the administration of antioxidants improved the changes in the enzymes and the morphological changes of the liver caused by NaF.

Green tea extract known to increase antioxidative enzymes and act as antioxidants to remove reactive oxygen species (Forester and Lambert, 2011). Furthermore, Sinha et al., (2007) revealed that green tea extract causes DNA repair by the high expression of DNA repair enzymes. Also Han et al. (2011) reported significant decrease in DNA damage with GTE intake for 28 days. Pandurangan et al (2012) revealed that green tea extract can protect from genotoxicity and lipid peroxidation in rats.

5. Conclusion

From the results of the present study it can be concluded that the use of green tea extract (GTE) improved the biochemical, histopathological and immunohistochemical changes that occur in the intestinal mucosa by fluoride (NaF) administrated and could be attributed to oxidative stress state.

6. Conflicts of interest
