Abstract

It is a reality that future development in the energy sector is founded on the utilization of renewable and sustainable energy sources. These energy sources can empower to meet the double targets of diminishing greenhouse gas emissions and ensuring reliable and cost-effective energy supply. Fuel cells are one of the advanced clean energy technologies and have demonstrated their ability to be a decent substitute to address the above-mentioned concerns. They are viewed as reliable and efficient technologies to operate either tied or non-tied to the grid and power applications ranging from domestic, commercial to industrial. Among different fuel cell technologies, proton exchange membrane is the most attractive. Its connection to the utility grid requires that the power conditioning system serving as the interface between the stack and the grid operates accordingly. This study aims to model and control a power conditioning system for the grid-connection of a megawatt fuel cell stack. Besides the grid, the system consists of a 1.54 MW/1400 V DC proton exchange membrane fuel cell stack, a 1.3 MW/600 V three-level diode clamped inverter and an LCL filter which is designed to reduced harmonics and meet the standards such as IEEE 519 and IEC 61000-3-6. The power conditioning control scheme comprises voltage and current regulators to provide a good power factor and satisfy synchronization requirements with the grid. The frequency and phase are synchronized with those of the grid through a phase-locked-loop. The modelling and simulation are performed using Matlab/Simulink. The results show good performance of the proposed microgrid as well as the inverter design and control approach with a low total harmonic distortion of about 0.35% for the voltage and 0.19% for the current.

Keywords: Fuel Cell; Grid-Connected Multi-Level Inverter; Grid Synchronization; Passive Filter; VSI Control.

1. Introduction

Energy sources dependent on oil, natural gas and coal have demonstrated their capacities to permit economic development. However, with the fast exhaustion of fossil fuels, the expansion of the world energy demand and concerns over global warming, new energy systems dependent on renewable and other sustainable energy are gaining more interests. It is now a reality that future development in the energy sector is basically founded on the utilization of renewable and sustainable energy sources. In this way, moving to sustainable energy sources can empower to meet the double targets of diminishing greenhouse gas emissions, by that overcoming extreme weather conditions and ensuring reliable and cost-effective energy supply. Fuel cells are one of the advanced clean energy technologies and have demonstrated their ability to be a decent substitute to address the above-mentioned concerns. They are viewed as reliable and one of the most efficient technologies as their efficiency ranges between 40 and 60% while the efficiencies of other technologies are lower [1]. A common fuel cell system utilizes hydrogen to produce power with heat and pure water as the by-product [2]. Various types of fuel cells can be found in market including proton exchange membrane fuel cell (PEMFC) alkaline fuel cell (AFC), phosphoric acid fuel cell (PAFC), molten carbonate fuel (MCFC) cell, direct methanol fuel cell (DMFC), solid oxide fuel cell (SOFC), however, proton exchange membrane fuel cell (PEMFC) is the most appealing in view of its low operating temperature, low noise, high efficiency and low pollution. As of now, PEMFC technologies have grown such that it is possible to acquire a megawatt power module and connected it to the utility grid [3].

In general, PEMFC produces DC (direct current) power at a low voltage level. To acquire high power fuel cell systems, PEMFCs are associated in series and parallel to form multi-stacks fuel cell systems. For grid-tied operation mode, a power converter is required to condition the generated DC voltage and converts it to AC power with synchronized frequency and phases. This power converter can also permit the control of power quality and power supply. A power converter can be either a DC-to-DC converter or an inverter or both depending on the load. A common power converter needs to comply with the following specifications [4]:

High gain,

Small current ripple,

High efficiency and low costs.

Several ways exist to connect fuel cell systems into an AC utility grid using power converters, the most popular configurations are [5]:

Centralized configuration,

String configuration

Multi-string configuration

Centralized and string configurations (Fig. 1A and 1B) can provide the similar output power without a converter to boost the output voltage of the fuel cell. However, their principal issue is the low output voltage in case it is fully loaded and high voltage when there is no-load [6]. A solution to overcome this issue is to connect a DC-to-DC voltage regulator before the inverter (Fig. 1C) to keep the voltage constant at the DC-link, thereby suppressing the dependence of the inverter input voltage on the load current. In such a case, a DC-to-DC boost converter can be associated to each fuel cell and the steady DC outputs of these converters can be connected in parallel. The benefits of this configuration include:

Each fuel cell can be controlled independently with the DC-to-DC converter;

The stack can be disconnected from the system for maintenance or replaced while the remainder of the system is kept operating;

The system's reliability can be improved alongside with fault-tolerant operations by including redundant fuel cell stacks with DC-to-DC converters;

Each subsystem can be designed independently and combined as required.

However, the capital cost involved is very.

The topology adopted in this study is centralized configuration (Fig. 1A). Different types of inverter ranging from low to high level can be used in centralized configuration depending on the power requirement. For low power and low voltage applications, the two-level inverter configuration is the most used topology whereas for high power and high voltage applications, multi-level inverter configuration is more suitable. Applications of multi-level inverters range from medium to high voltage and comprise power distribution, motor drives, etc. For a given application, the choice of appropriate multi-level topology and its control scheme are not defined and depend on various engineering compromises, however, the most developed multi-level inverter topologies include the Diode Clamped, the Flying Capacitor and the Cascade Full Bridge inverters.

Diode Clamped multilevel inverter is the most accepted topology; the concept behind this inverter is to use diodes to limit the power devices voltage stress. The voltage at each capacitor and each switch is V_{dc} . An n -level inverter requires $(n-1)$ voltage sources, $2(n-1)$ switching devices and $(n-1)(n-2)$ diodes. By enlarging the number of voltage levels, the output voltage quality is improved, and the voltage waveform is nearly sinusoidal. The voltage across each capacitor is $V_{dc}/2$ and each device voltage stress will be limited to one capacitor voltage level $V_{dc}/2$ through clamping diodes. The three-level diode clamped inverter is one of the most available topologies in the market; it is widely used in industrial applications in the range of 2.3 to 6.6 kV.

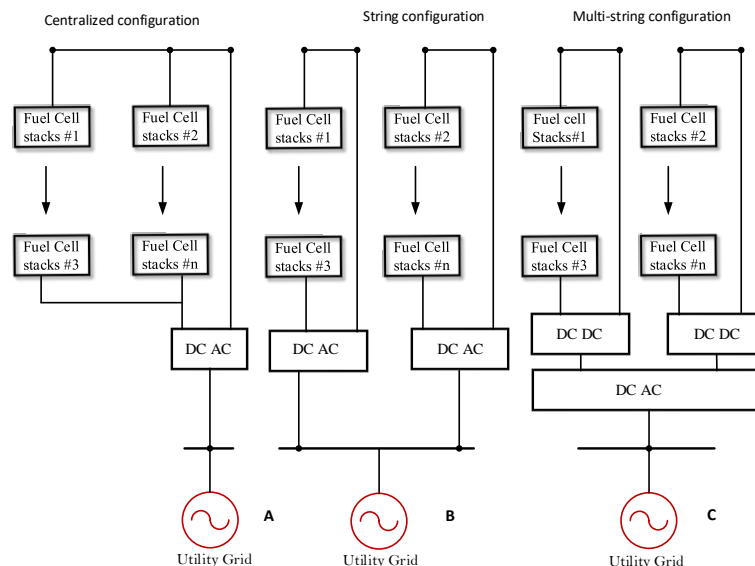

Fig. 1: Topologies for Grid-Connected Fuel Cell Systems: (A) Centralized Configuration, (B) String Configuration and (C) Multi-String Configuration. [7].

A common inverter generates harmonics as its output voltage or current is not a pure sine wave. In general, harmonics are caused by non-linear loads, drawing non-sinusoidal current from sinusoidal voltage sources. These loads include power electronics converters, motor drives and electric arc furnaces. Loads including fluorescent lamps, computers, fax machines, photocopiers, laser printers, battery chargers, etc. are also sources of harmonics. These harmonics impact negatively on sensitive equipment above several kilowatts of the connected loads [8]. Standards such as IEEE 519 and IEC 61000-3-6 set the allowable harmonic distortion for both the current and the voltage in a power system based on the current level and the voltage level respectively. Conventional criteria used to reduce harmonics is the use of an input inductance while the output inductance of the power conversion devices serves as filters. However, due to the increase in the size of systems, realizing practical filters becomes difficult due to high cost and poor system dynamic response. An LCL filter is connected after the inverter to eliminate harmonics resulting from the inverter switching. In comparison with other filters such as an L and LC filters, an LCL filter has the benefit of achieving better attenuation capacity for complex harmonics and has better dynamic characteristics [9,10]. However, an LCL filter can cause instability problems because of its zero impedance which may create resonance for some frequencies. To overcome this issue, various damping techniques such as incorporating a physical passive element in series with the filter capacitor [11] have been proposed. Among these damping techniques, the technique using a passive element is simple and reliable, however, the passive element causes power loss and weakens the effect of the LCL filter which can be overcome by using an active damping technique [12].

Inverters can operate either in off-grid or grid-connected mode. When operating in grid-connection mode, the inverter output voltage and frequency should be the same as those of the grid. Hence, the current injected into the grid should be balanced, sinusoidal, and have a total harmonic distortion lower than 5% [13]. To achieve these requirements, the control of the inverter plays a vital role and in such a case, the objective of the control action is to properly feed the extracted power to the grid. To obtain higher performance several control strategies for grid-connected inverters have been proposed, such as selective harmonics elimination pulse-width modulation (SHE-PWM), pulse-width modulation (PWM) and optimized harmonics stepped pulse-width modulation (OHS-PWM) [14], however, this research focuses on

the PWM control approach. The PWM control approach can be grouped into open loop and closed loop control systems; the open-loop PWM techniques are SPMW, space vector PWM, sigma-delta modulation, while closed loop current control methods. For grid-connected inverters, the closed loop control consists three major steps namely the outer loop control, inner loop control and synchronization. The outer control loop can be a DC-link voltage control or a power control loop, which generates the inner current references, on the other, the inner current loop regulates the injected currents, while the synchronization is achieved through a phase-locked-loop (PLL) which uses the grid to provide the correct phase and frequency.

This research aims to model and control a three-level diode clamped inverter for grid-connected megawatt fuel cell applications. The considered system includes a 1.54 MW/1400 V DC proton exchange membrane fuel cell stack, a 1.3 MW/600 V three-level diode clamped inverter and an LCL with a total voltage harmonic distortion of 0.5 %. The inverter control scheme comprises voltage and current regulators to provide a good power factor and satisfy synchronization requirements with the grid. The frequency and phase are synchronized with those of the grid through a phase-locked-loop. Modelling and simulation are performed using Matlab/Simulink.

The rest of the paper is organized as follows: Section 2 deals with the description and modelling of the grid-tied megawatt fuel cell system, Section 3 focuses on the results and discussion and the last Section gives the conclusion.

2. Grid-tied megawatt fuel cell description and modelling

2.1. Description

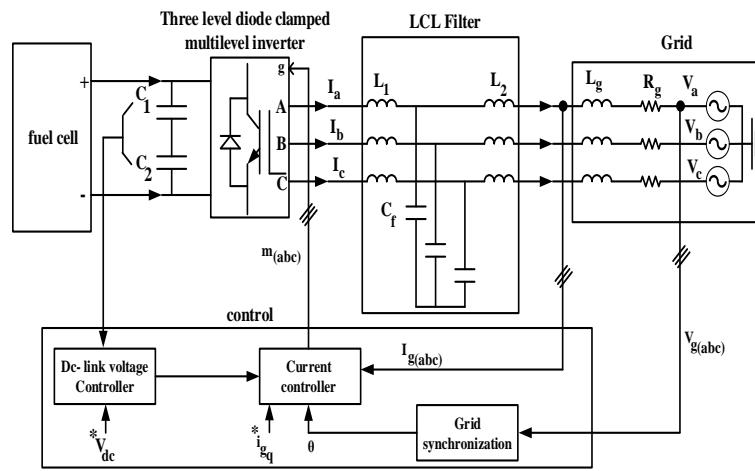

Fig. 2: Layout of Grid-Connected Megawatt Fuel Cell Stack.

The topology adopted in this study is the centralized configuration, whereby the megawatt proton exchange membrane fuel cell (PEMFC) stack is connected to the grid directly through the inverter without the use of DC-to-DC converters. As depicted in Fig.2, besides the megawatt PEMFC stack, the system includes a three-level diode clamped inverter and a power filter unit connecting the system to the grid. The megawatt stack is realized through series and parallel connection of individual PEMFC stacks. Each PEMFC stack generates 126 kW at 1400 Vdc. The overall power of the megawatt multi PEMFC stack fuel cell is 1.54 MW. A three-level diode clamped inverter converts the 1400 DC voltage of the fuel cell to AC to supply a local load and feed any excess into the utility grid depending on the generation conditions. To mitigate the effects of harmonics voltage and current, an LCL filter is interfaced between the inverter, the local load and the grid.

2.2. Modelling

2.1.1. Modelling of PEMFC

The output voltage of a PEMFC consists of four terms namely Nernst potential E_{Nernst} , activation potential V_{act} , concentration difference potential V_{con} and V_{ohmic} [15], [16]. This output voltage is expressed as follows:

$$V_{FC} = E_{Nernst} - V_{act} - V_{ohm} - V_{Con} \quad (1)$$

$$E_{Nernst} = 1.229 - 0.8510^{-3}(T - 298.15) + 4.308510^{-5} \times T \ln \left[P_{H_2} \frac{P_{O_2}^{0.5}}{P_{H_2O}} \right] \quad (2)$$

$$V_{act} = -[\zeta_1 + \zeta_2 T + \zeta_3 T \ln(C_{O_2}) + \zeta_4 T \ln(i_{FC})] \quad (3)$$

$$C_{O_2} = \frac{P_{O_2}}{5.08 \times 10^6 \exp(-498/T)} \quad (4)$$

$$L_{ohm} = i_{FC} (R_m + R_c) \quad (5)$$

$$R_m = \frac{\rho_m l}{A} \quad (6)$$

$$\rho_m = \frac{(181.6[1 + 0.03(\frac{i_{FC}}{A})] + 0.062(\frac{T}{303})^2(\frac{i_{FC}}{A})^{2.5}}{[\Psi - 0.634 - 3(\frac{i_{FC}}{A})] \exp(\frac{4.18 \times (T - 303)}{T})} \quad (7)$$

$$V_{\text{conc}} = -B \cdot \ln \left(1 - \frac{J}{J_{\text{max}}} \right) \quad (8)$$

$$J = \frac{I_{\text{FC}}}{A} \quad (9)$$

The parameters, physical meaning with units and value used in the modelling of a PEMFC stack are given in Table 1 [17], while Table 2 shows the general characteristics of the obtained Megawatt fuel cell stack.

Table 1: Single PEMFC Parameters

| Parameter | PEMFC stack Physical meaning and units | Value |
|-----------------|---|------------------------|
| T | Stack temperature °K | 338 |
| A | Activation area cm ² | 50.6 |
| L | Membrane thickness μm | 178 (Nation 117) |
| P _{H2} | Hydrogen pressure atm (0.1 MPa) | 1 atm |
| P _{O2} | Oxygen pressure atm (0.1MPa) | 1 atm |
| R _C | Membrane contact resistor Ω | 0.0003 |
| B | Coefficient for computing V _{con} | 0.016 |
| ζ ₁ | Curve fitting parameter | -0.948 |
| ζ ₂ | Curve fitting parameter | 0.00312 |
| ζ ₃ | Curve fitting parameter | 7.6x10 ⁻⁵ |
| ζ ₄ | Curve fitting parameter | -1.93x10 ⁻⁴ |
| Ψ | Membrane moisture content | 23 |
| I _L | Current density driven from PEMFC mA/cm ² | 1500 |
| C _{O2} | O ₂ concentration at the cathode /(mole/cm3) | - |

Table 2: Megawatt PEMFC Parameters

| Parameter | Megawatt PEMFC stack | |
|---|----------------------|----------|
| | Value | Unit |
| Stack nominal power | 126000 | W |
| Stack maximum power | 134400 | W |
| Fuel cell resistance | 8.2936 | Ohms (Ω) |
| Nerst voltage of a stack E _n | 1.1039 | V |
| Nominal utilization: | | |
| Hydrogen (H ₂) | 98.47 | % |
| Oxygen (O ₂) | 99.99 | % |
| Nominal consumption: | | |
| Fuel | 1259 | Slpm |
| Air | 2985 | Slpm |
| Exchange current (i ₀) | 12.8226 | A |
| Exchange coefficient (alpha) | -0.38762 | - |
| Fuel cell signal variation parameters: | | |
| Fuel cell composition (x_H2) | 99.56 | % |
| Oxygen composition (y_O2) | 21 | % |
| Fuel flow rate at nominal hydrogen utilization: | | |
| Nominal | 1056 | lpm |
| Maximum | 1970 | lpm |
| Air flow rate at nominal hydrogen utilization: | | |
| Nominal | 3700 | lpm |
| Maximum | 6907 | lpm |
| System temperature (T) | 338 | Kelvin |
| Fuel supply pressure (P _{fuel}) | 10.5 | bar |
| Air supply pressure (P _{air}) | 1 | bar |
| Number of cells | 2000 | - |
| Nominal stack efficiency | 55 | % |
| Number of stacks | 12 | |
| Megawatt fuel cell voltage at 0A | 2000 | V |
| Megawatt fuel cell voltage at 1 A | 1800 | V |
| Megawatt stack nominal power | 1.4 | MW |
| Megawatt stack nominal current | 1100 | A |
| Megawatt fuel cell nominal operating point of the current | 90 | A |
| Megawatt fuel cell nominal operating point of the voltage | 1400 | V |
| Megawatt fuel cell maximum operating point of the current | 168 | A |
| Megawatt fuel cell Maximum operating point of the voltage | 800 | V |

2.1.2. Modelling of three-level diode clamped inverter

A typical three-level diode clamped inverter is composed of twelve switches and six clamping diodes as shown in Fig. 3. The DC-link capacitor is separated into two parts, and the midpoint between the upper and lower parts is known as the neutral point. The six diodes called clamping diodes connect the output of each leg of the inverter to the neutral point. The three-level diode clamped inverter is based on a series connection of four switches in each leg. In comparison with a two-level inverter, the rated voltage of the used switch can be reduced by half, making it appropriate for a high voltage and large capacity system.

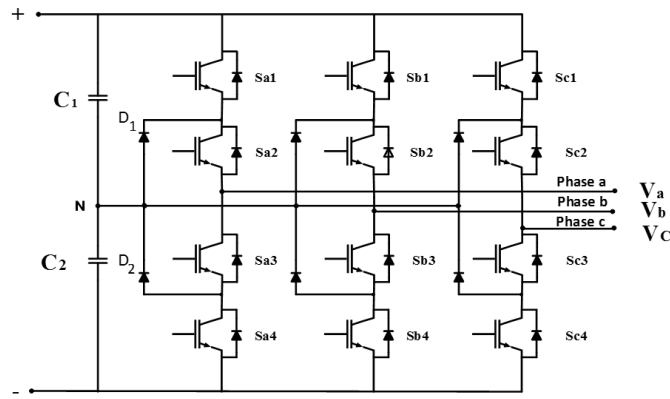

Fig. 3: Topology of Three-Level Inverter. [18].

The switching operation of a three-level diode clamped inverter is shown in Table 3, whereby if the switches S_{a1} and S_{a2} are turned on and S_{a3} and S_{a4} are off, the output voltage is $+V_{dc}/2$. On the contrary, the output voltage is $-V_{dc}/2$. On the other hand, if S_{a1} and S_{a4} are off and S_{a2} and S_{a3} are on, the output voltage is zero [4], [19].

Table 3: Switching States of A Three-Level Diode Clamped Inverter

| Switching state | Switching device state | | | Out pole voltage V_{xn} (with $x = a, b, c$ and $n = \text{neutral}$) |
|-----------------|------------------------|----------|----------|--|
| | S_{a1} | S_{a2} | S_{a3} | |
| P | ON | ON | OFF | $+V_{dc}/2$ |
| O | OFF | ON | OFF | 0 |
| N | OFF | OFF | ON | $-V_{dc}/2$ |

The switching state of each leg can be expressed as P, N and O. Hence, it is possible to represent the three-leg output voltage utilizing the switching states of the three legs. In total, there are 27 switching states that can be represented by the three-leg output voltage, and these 27 switching states can be expressed as vectors as shown in Fig. 4.

Fig. 4: Voltage Vector of Three-Level Inverter. [20].

The voltage vector diagram of a three-level inverter is divided into six sectors (Fig.4). Each of these sectors can be separated into four parts, which are expressed as regions 1–4. In the space vector pulse-width modulation (PWM) method, the command voltage vector is obtained from the output voltage of the three-level converter.

The command voltage vector can be expressed using the magnitude (V_{ref}) and phase (θ) as shown in the equation (10).

$$\vec{V}_{ref} = V_{ref} e^{j\theta} \tag{10}$$

By considering only one sector (Sector I), the equations of voltage vectors V_1 , V_2 , and V_7 are expressed as follows:

$$\vec{V}_1 = \frac{1}{3} V_{dc}$$

$$\vec{V}_2 = \frac{1}{3} V_{dc} e^{j\pi/3}, \tag{11}$$

$$\vec{V}_7 = \frac{\sqrt{3}}{3} V_{dc} e^{j\pi/6}$$

The effective time of the selected valid vectors is determined so that the average output voltage during a switching period (T_s) becomes equal to the command voltage vector (V^*) [4]. Therefore, the following equations must be satisfied:

$$\vec{V}_{ref} T_s = \vec{V}_1 T_1 + \vec{V}_2 T_2 + \vec{V}_7 T_7 \quad (12)$$

$$T_s = T_1 + T_2 + T_7 \quad (13)$$

Where T_1 , T_2 , and T_7 are the effective switching time of the selected voltage vector V_1 , V_2 and V_7 respectively. By combining (10), (11) and (12), the following equation is obtained:

$$V_{ref} e^{j0} T_s = \frac{1}{3} V_{dc} T_1 + \frac{\sqrt{3}}{3} V_{dc} e^{j\pi/6} T_2 + \frac{1}{3} V_{dc} e^{j\pi/3} T_7 \quad (14)$$

The obtained parameters of the inverter are given in Table 4

Table 4: Inverter Parameters

| Parameters | Value |
|---|-------------|
| DC link voltage (V_{DC}) | 1400 V |
| Output power of the inverter | 1.3 MW |
| Line-to-line RMS voltage (V_{LL}) | 600 V |
| Phase voltage (V_{PH}) | 346 V |
| Nominal current (I_{RMS}) | 1200 A |
| Power factor (P_f) | 0.95 |
| Peak-to-peak current (I_{Max}) | 1630.22 A |
| Switching frequency (f_{sw}) | 2000 Hz |
| Grid frequency (f_g) | 50 Hz |
| Modulation range (m_a) | 0.7 |
| Attenuation factor (K_a) | 20 % |
| Maximal power factor variation acceptable by grid | 5 % |
| Inverter configuration | Three-phase |
| Phase-to-ground inverter voltage before filter | 930 V |
| Output current before the filter | 1200 A |

2.1.3. Modelling of LCL filter

The role of the LCL filter is to reduce high-order harmonics from the output of the inverter, however, poor design can result to an increased total harmonic distortion. Fig. 5 displays a typical model of an LCL filter, where L_i is the inverter side inductor, L_g is the grid side inductor, R_i and R_g are inductors series resistance, C_f is the filter capacitance, R_f is the damping resistance, V_i is the inverter input voltage, V_g is the output voltage of the system (grid voltage), I_i is the inverter output current, I_g is the grid current and I_c is the capacitor current.

Fig. 5: Model of an LCL Filter. [21].

The filter transfer function can be expressed as:

$$H_{LCL} = \frac{I_g}{V_i} \quad (15)$$

Where the grid voltage is assumed to be an ideal voltage source capable of damping all the harmonic frequencies. If $V_g=0$, the transfer function is expressed as follows [22]:

$$H_{LCL} = \frac{1}{L_i L_g C_f s^3 + (L_i + L_g) s} \quad (16)$$

By including the damping resistance, the transfer function is, furthermore, expressed as [22]:

$$H_{dLCL} = \frac{C_f R_d s + 1}{L_i C_f s^3 + C_f (L_i + L_g) R_d s^2 + (L_i + L_g) s} \quad (17)$$

Several characteristics are taken into account in the design of an LCL filter, such as filter size, current ripples and switching ripple attenuation. The reactive power demands can result to a resonance of the capacitor interacting with the grid. Hence, passive or active damping are added by including a resistor in series with the capacitor. In this study, the passive damping option is adopted, however, active damping can also be considered [23–25]. The base impedance and base capacitance Z_b and C_b are given by (18) and (19) as follows:

$$Z_b = \frac{U_n^2}{P_n} \quad (18)$$

$$C_b = \frac{1}{\omega_g Z_b} \quad (19)$$

Where is P_n is the output power of the inverter, U_n the line-to-line voltage and ω_g the system's frequency.

The filter capacitance C_f serving as a sink for harmonics with high frequency is calculated by setting a percentage of not more than 5% of the base capacitance C_b [26]. This study considers that percentage as equal to 5%. The filter capacitance is given by (20) as follows:

$$C_f = X \cdot C_b \quad (20)$$

The maximum current ripple at the output of the inverter is given by (21) [27]:

$$\Delta I_{Lmax} = \frac{2V_{DC}}{3L_i} (1-m)mT_{SW} \quad (21)$$

Where V_{DC} is the DC link voltage, $T_{SW} = \frac{1}{f_{SW}}$ is the period, and (m) is the inverter modulation often between 0 and 1. In this study, m is selected equal to 0.57. With $m=0.57$, (21) becomes [28]:

$$\Delta I_{Lmax} = \frac{0.49 \cdot V_{DC}}{3L_i \cdot f_{SW}} \quad (22)$$

Inverter side current ripple (ΔI) percentage is limited between 10 to 25% of the peak output current (I_{max}), thus, ΔI_{Lmax} can be expressed as:

$$\Delta I_{Lmax} = (1\% - 5\%) \cdot I_{max} \quad (23)$$

This study considered ΔI_{Lmax} as 1%, hence, $\Delta I_{Lmax} = 0.01 I_{max}$.
Where

$$I_{max} = \frac{P_n \sqrt{2}}{3V_{ph}} \quad (24)$$

From (23), L_i can be expressed as:

$$L_i = \frac{0.49 V_{DC}}{3 \Delta I_{Lmax} \cdot f_{SW}} \quad (25)$$

Where f_{WS} is the switching frequency

The LCL filter must reduce the current ripple up to 20%, resulting in a ripple value of about 5% of the output current [27,29]. Equation (26) gives the harmonic current generated by the inverter with the one from the grid as:

$$\frac{I_g(h)}{I_i(h)} = \frac{1}{|1+r[1-L_i C_b \omega_{SW}^2 X]|} K_a \quad (26)$$

Where, K_a is the desired attenuation and r is the ratio between the inductance at the inverter side and the grid side. This ratio is given as:

$$L_i = r L_g \quad (27)$$

The grid inductance is expressed by (28) as follows:

$$L_g = \frac{\sqrt{\frac{1}{K_a^2} + 1}}{C_f \omega_{SW}^2} \quad (28)$$

The resonant frequency ω_{res} and the damping ratio (ζ) of the LCL-filter are obtained as [29]:

$$\omega_{res} = \sqrt{\frac{L_i + L_g}{L_i L_g C_f}} \quad (29)$$

$$\zeta = \frac{C_f \omega_{res} R_d}{2} \quad (30)$$

The resonant frequency for the LCL filter can be determined as:

$$f_{res} = \frac{1}{2\pi} \sqrt{\frac{L_i + L_g}{L_i L_g C_f}} \quad (31)$$

This frequency is often set to satisfy (32) given as:

$$10f_g < f_{res} < 0.5f_{SW} \quad (32)$$

In case (32) is not satisfied, parameters must be recalculated, and the value of the damping resistor can be calculated as:

$$R_f = \frac{1}{3\omega_{res} C_f} \quad (33)$$

Table 5 gives the filter parameters obtained.

Table 5: LCL Filter Design Parameters

| Parameters | LCL filter design value |
|--|-------------------------|
| Inverter side inductor (L_i) | 0.9 mH |
| Grid side inductor (L_g) | 0.072 mH |
| Capacitor filter (C_f) | 531 μ F |
| Damping resistance (R_f) | 0.118 Ω |
| Resonant frequency (f_{res}) | 845 Hz |
| Inductors resistances ($R_i=R_g$) | 0.00761 Ω |
| Sampling frequency (f_s) | 10000 Hz |
| Output power of the inverter (P_n) | 1.3 MW |
| Line-to-line RMS voltage (U_n) | 600 V |

2.1.4. Modelling inverter control

Outer control loop

Fig. 6 shows the outer control loop; the DC-link voltage is regulated to control the power of the inverter using an outer loop control. This voltage regulation provides desired power transfer. DC voltage controller provides reference current i_d^* for the inner controller. The current reference I_q^* is set to zero for unity power factor [30].

The DC-link voltage is kept constant, especially, in case of double-stage configurations where the DC-link voltage is controlled at a desired level. To guarantee an appropriate power injection to the grid, the DC-link voltage must be at least higher than the grid peak voltage.

Fig. 6: DC-Link Voltage Controller Block Diagram. [31]

The energy stored in the dc-link capacitor is expressed as follows:

$$E_{DC-link} = \frac{1}{2} C_{DC-link} V_{DC}^2 \tag{34}$$

Where $C_{DC-link}$ is the capacitance of the DC-link capacitor and $V_{dc-link}$ is the voltage across the DC-link capacitor. The total voltage across DC-link capacitor should be greater than $V_{DC-min} = \frac{2\sqrt{2}}{\sqrt{3}} V_{LL}$ to obtain V_{LL} at output of the inverter. DC voltage controller consists of PI controller to keep the V_{DC} equal to V_{ref} [32]. The response time of outer voltage control is slow as compare to current controllers. The bandwidth of voltage controller is set between 0 to 20Hz. The calculated PI controller parameters K_{pv} and K_{iv} of voltage controller are given in Table 6.

Table 6: Outer Control Loop Parameters

| Parameter | Value |
|--|---------------|
| DC-link capacitor (C_{DC}) | 50000 μ F |
| Proportional gain of controller (K_{pv}) | 133.5 |
| Integral gain of controller (K_{iv}) | 303,409.1 |

Inner control loop

The inner control loop (Fig. 7) takes the error between reference currents generated by the outer control loop and measured currents. The error is fed into the PI controller. The inner control loop must be designed such that it has high bandwidth to give fast response [33]. The transfer function of inner control loop is expressed in (35) and the parameters of the controller are given in Table 7.

$$F(S) = \frac{1}{T_s s(T_s s + 1) + 1} \tag{35}$$

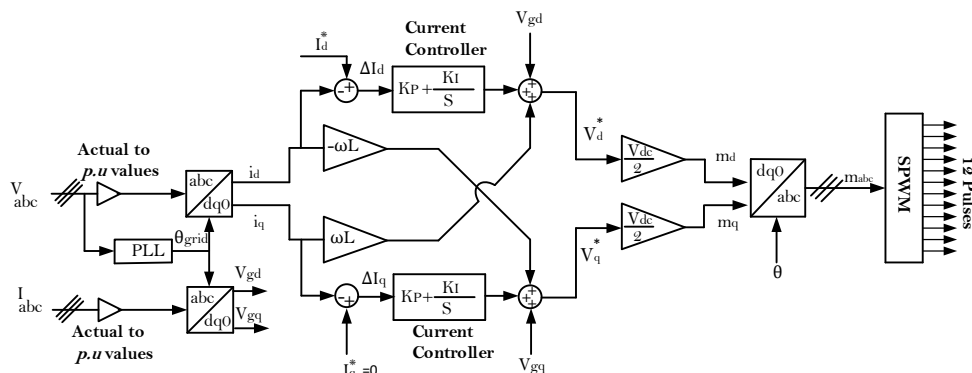

Fig. 7: Inner Control Loop. [5].

The output of the inner control loop (md and mq) are transformed from dqo frame to abc to obtain the modulation which is fed into the PWM generator to produce the sinusoidal pulse width modulation signal (SPWM) then drive then inverter. For the three-level inverter, twelve pulses are required.

Table 7: Inner Control Loop Parameters

| Parameter | Value |
|--|--------|
| Proportional gain of controller (K_{pc}) | 3.24 |
| Integral gain of controller (K_{ic}) | 50.625 |

Grid synchronization

Various synchronization techniques have been reported in the literature, among which the most commonly employed technique is based on the phase-locked loop (PLL) method. Compared to other synchronization techniques, the PLL can deliver rapid and exact synchronization information with a high degree of immunity and insensitivity to disturbances, harmonics, unbalances, sags/swells, notches and other types of distortions in the input signal. Fig.8 shows a typical diagram of PLL. The injected output current of the converter must be synchronized with utility voltage [34]. Hence, the synchronization control of extracting angle of grid voltage plays an essential role in grid-connected inverter. The closed-loop transfer function of the PLL is given as follows:

$$G_{CL-PLL}(S) = \frac{\theta^*}{\theta} = \frac{K_1 s + K_2}{s^2 + K_1 s + K_2} \tag{36}$$

Where K_1 and K_2 are respectively the proportional and integral gain of the PI-based loop filter given in Table 8.

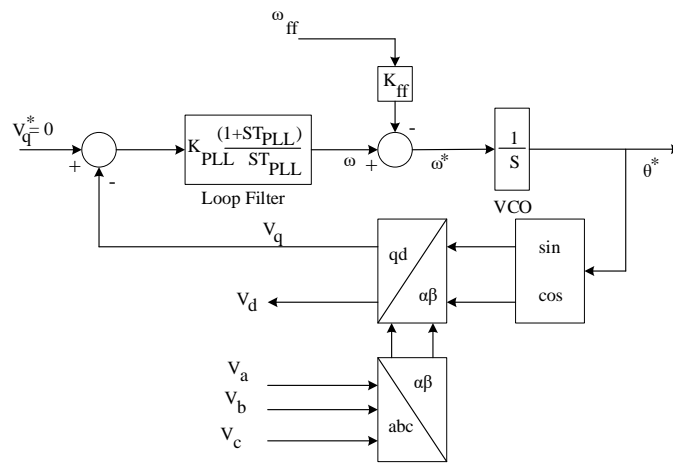

Fig. 8: PLL Block Diagram. [35].

Table 8: PLL Based Loop Filter Parameters

| Parameter | Value |
|---|----------|
| Proportional gain of controller (K_1) | 9.7 |
| Integral gain of controller (K_2) | 22045.45 |

3. Results and discussion

The system described in section 2.1 was simulated using Matlab/Simulink software for a duration of 2.5 seconds to assess its performance based on parameters provided in Tables 4, 5,6,7 and 8. The megawatt fuel cell system was considered to operate in grid-tied mode. Furthermore, it was assumed that during the simulation, the hydrogen and oxygen composition, system temperature, hydrogen and oxygen pressure were unchanged.

The results from the simulation are presented in two parts namely the DC and AC parts. The DC side comprises the voltage, current and power generated by the megawatt stack then fed into the DC link, while the AC side consists of the output characteristics of the inverter, filter and the control.

The DC link voltage is displayed in Fig. 9; this voltage has some overshoot at the beginning of the simulation, subsequently gets to the stable value of 1400 V which is equal to the reference DC link voltage. The voltage has a rising time of about 5 milliseconds corresponding to the time needed for the voltage to rise from 0 to 100 % of its final value. Additionally, the overshoot and undershoot of the voltage at the beginning of the simulation are 115.864 % and 1.939 % respectively before getting to its stable value. Similarly, the DC current presents an overshoot and undershoot at the beginning of the simulation are 1.970 % and 68.052 % respectively. On the other hand, the power response, it has a rising time of about 22.437 milliseconds, while the overshoot and undershoot of the voltage at the beginning of the simulation are 11.741 % and 3.217 % respectively, before getting to its stable value.

Fig. 9: DC-Link Voltage.

The AC voltage is a three-level signal with the line to line value swinging between $-V_{DC}$ link to $+V_{DC}$ link as depicted in Fig. 10. This AC voltage is obtained at the output of the inverter without a filtering device. Its peak to peak value is about 2800 V, hence, the maximum and minimum values are +1400 V and -1400 V respectively (see Fig. 10), while the RMS voltage is about 938 V. The signal shown is in the form of pulses with varying widths according to the amplitude of the reference sine wave. The fundamental frequency of this signal is equal to that of the grid frequency, which is 50 Hz.

The rise time of the phase to phase voltage is about 3.841 milliseconds, while the fall time is 3.971 milliseconds. Additionally, the overshoot and undershoot of the voltage at the beginning of the simulation are 0.49 % and 25.347 % respectively.

The phase-to-phase voltage of the three-level inverter shown in Fig. 10 is subjected to harmonics caused by the switching of power electronics devices in the inverter. These harmonics negatively impact on the system and can cause problems such as low efficiency, poor power factor, transient, etc. Standards such as IEEE 519 and IEC 61000-3-6 define the allowable harmonic distortion for both the current and the voltage in a typical power system based on the current level and the voltage level respectively. The allowable voltage total harmonic distortion is defined in terms of voltage level, while the current total demand distortion limit is expressed as a function of the voltage level and the ratio of the short circuit current to the rated load current. IEEE 519-2014 defines the total harmonic distortion as the ratio of the root mean square of the harmonic content, considering harmonic components up to the 50th order and specifically excluding inter harmonics, expressed as a percent of the fundamental.

On the other hand, the total demand distortion is the ratio of the root mean square of the harmonic content, considering harmonic components up to the 50th order and specifically excluding inter harmonics.

The phase-to-phase voltage total harmonic distortion is depicted in Fig. 11; its value is around 44.99% for frequencies up to 5 kHz when the fundamental is 50 Hz. This percentage is far above the limit as set by standards. With such a distortion, a load can be subjected to fast deterioration, furthermore, the lifespan of the fuel cell can also be shortened, hence, the filtering of the inverter voltage waveforms is required.

The phase-to-phase voltages V_a , V_b , and V_c and the current I_a , I_b and I_c after the passage into the low-pass LCL filter are shown in Fig. 12. As expected, magnitudes of the phase voltages are about 600 V, while the magnitudes of the phase currents are around 1200A. The rise time of the phase to phase voltage is about 5.867 milliseconds, while the fall time is 5.866 milliseconds. Additionally, the overshoot and undershoot of the voltage at the beginning of the simulation are 0.206 % and 1.985 % respectively.

Similarly, the rise time of the phase current is about 5.856 milliseconds, while the fall time is 5.854 milliseconds. Additionally, the overshoot and undershoot of the voltage at the beginning of the simulation are 0.284 % and 1.985 % respectively.

Fig. 10: Output Voltage of Three-Level Diode Clamped Inverter.

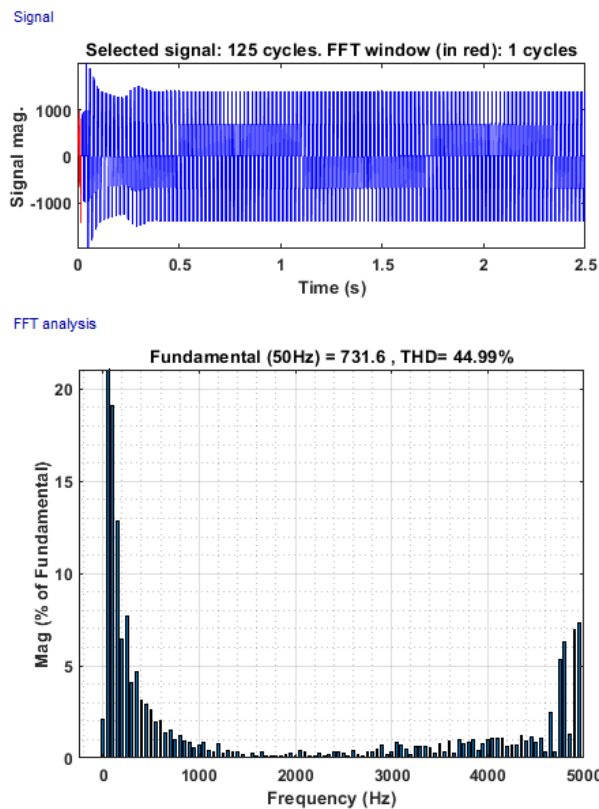

Fig. 11: Phase-To-Phase Voltage Harmonic Distortion Before Filtering.

Fig. 13 and Fig. 14 depict the histograms of voltage total harmonic distortion and current harmonic distortion at the output of the LCL filter respectively. These charts are obtained for a 1.29 MW three-level inverter connected to the grid at 600 V. The starting time for both harmonics voltage and current measurement is at zero second. With the designed filter, both harmonics are considerably reduced. The corresponding voltage total harmonic distortion is about 0.35 % whereas the total harmonic distortion of the current is 0.19 %. The obtained values comply with the IEEE 519-2014 standards which states that the harmonic distortion limit for voltages less than 1 kV is 8 % [13]. On the other hand, IEEE 519-2014 defines the total demand distortion limit for voltages less than 69 kV and currents greater than 1000 A as equal to 20 % [13]. At a full load, both the total harmonic distortion and the total demand distortion are equal, hence, as the load was simulated at its full value, the corresponding total demand distortion is also equal to 0.19 %. This obtained value is conformed to the above-mentioned standards.

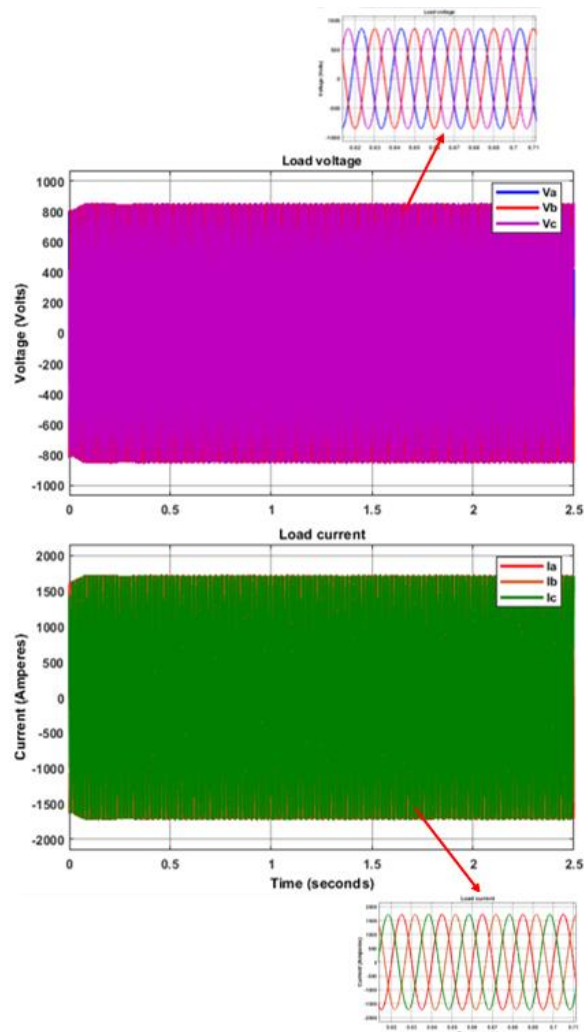

Fig. 12: Voltages and Currents After Filter.

Signal

FFT analysis

Fig. 13: Phase-To-Phase Voltage Harmonic Distortion After Filter.

The DC link voltage is displayed in Fig. 15a; this voltage is compared against the adopted reference voltage which is 1400 V to obtain the error for the design of the controller to generate the I_d reference. The I_d reference is then compared against the I_d from the grid (Fig. 15b)

to generate V_d reference. On the other hand, I_q reference is set to zero and compare against the grid I_q to generate V_q reference. Both V_d and V_q reference values are then modulated as m_d and m_q , then transformed to abc frame to generate the SPWM to drive the inverter.

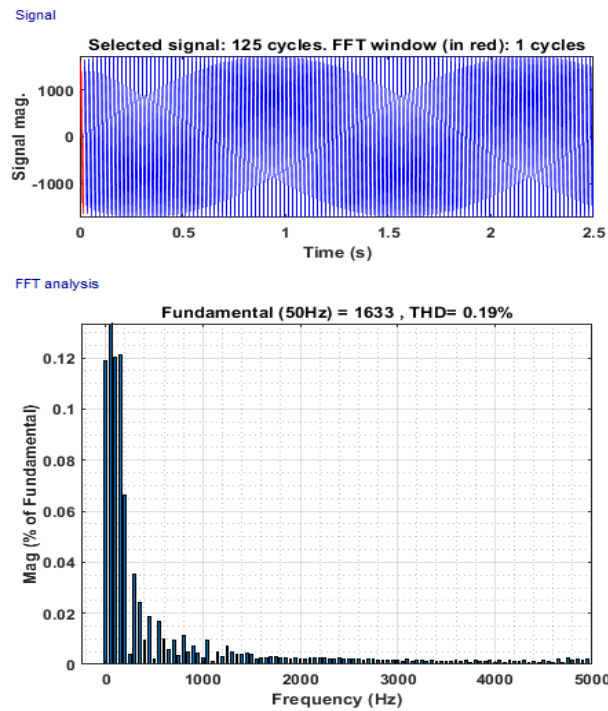

Fig. 14: Phase Current Harmonic Distortion after Filter.

Fig. 15: Comparison of (A) Outer Control Loop and (B) Inner Control Against Their Reference Values.

The load and the grid active and reactive power are shown in Fig 16; for the load, the active power is about 1.26 MW (Fig. 16a), while the reactive power varies around zero ($2.574e-8$ VAR) (Fig. 16b). At the beginning of the simulation, the load active power response is characterized by an overshoot of 14.935 % between the time $t = 0$ and $t = 0.3$ seconds and an undershoot of 2.468 % between $t = 0.3$ and $t = 0.4$ seconds, thereafter, this response stabilizes to reach the steady state value of 1.26 MW. On the other hand, the reactive power displays an overshoot of 215.301 %, whereas the undershoot is 2.332 %. Regarding the grid; the active power supplied is about 21 kW (Fig. 16c), while the reactive is 13 kVAR (Fig. 16d). These values represent the deficit power that the megawatt fuel cell is unable to supply to the load due losses occurring into the system, hence, the grid is operating as a support to complement the megawatt fuel cell system. The active power response provided by the grid to the load is characterized by an overshoot of 11.728 % between the time $t = 0$ and $t = 0.3$ seconds and an undershoot of 1.998 % between $t = 0.3$ and $t = 0.4$ seconds, thereafter, this response stabilizes to reach the steady state value of 21 kW. Similarly, the reactive power provided by the grid to the load displays an overshoot of 136.026 %, whereas the undershoot is 6.189 %.

Fig. 16: (A) Load active and reactive power and (B) Grid active and reactive power.

4. Conclusion

The future development in the energy sector is founded on the utilization of renewable and sustainable energy sources. These energy sources can empower to meet the double targets of diminishing greenhouse gas emissions and ensuring reliable and cost-effective energy supply. Fuel cells are one of the advanced clean energy technologies and have demonstrated their ability to be a decent substitute to address the above-mentioned concerns. They are viewed as reliable and efficient technologies to operate either tied or non-tied to the grid and power applications ranging from domestic, commercial to industrial. Among different fuel cell technologies, proton exchange membrane is the most attractive. Its connection to the utility grid requires that the power conditioning system serving as the interface between the stack and the grid operates accordingly. This study aimed to model and control a power conditioning system for the grid-connection of a megawatt fuel cell stack. The system consisted of a 1.54 MW/1400 V DC proton exchange membrane fuel cell stack, a 1.3 MW/600 V three-level diode clamped inverter and an LCL filter which is designed to reduced harmonics and meet the standards such as IEEE 519 and IEC 61000-3-6. The power conditioning control scheme comprised voltage and current regulators to provide a good power factor and satisfy synchronization requirements with the grid. The frequency and phase were synchronized with those of the grid through a phase-locked-loop. The modelling and simulation were carried out using Matlab/Simulink environment. The results showed good performance of the proposed system with a low total harmonic distortion of about 0.35% for the voltage and 0.19% for the current.

The phase-to-phase AC voltage obtained at the output of the inverter without a filtering device displayed a peak to peak value is about 2800 V, hence, the maximum and minimum values were + 1400 V and -1400 V respectively, while the RMS voltage was about 938 V. This voltage showed a total harmonic distortion of about 44.99% for frequencies up to 5 kHz when the fundamental is 50 Hz. This percentage was far above the limit as set by standards such as IEEE 519 and IEC 61000-3-6. To comply with the above-mentioned standards, an LCL low pass filter was designed connected at the output of the inverter. The phase-to-phase voltages and the current after filtering exhibited magnitudes of about 600 V and 1200A for the voltage and the current respectively.
