Abstract

The present work including laboratory and field experimental test to evaluate the efficiency of different insecticides (systemic and bio-icides). Laboratory works including different concentrations for Mitrixin, Levo, Evisect, Polo and Actara for *Ceroplasts rusci* L. insect in leaf. Mortality percentage reading after two days. Field works were including the best concentration of insecticides achieved the highest mortality percentage for nymphs and adults of *Ceroplasts rusci* in the tree. The Mortality percentage reading after one, two, seven, fourteen days.

Laboratory results showed that the efficiency of insecticides significantly variant is depending to concentration and type of insecticide. The corrected Mortality percentage was increased by increasing the concentration and type of insecticides. The Mortality percentage (59.23, 53.94, 52.25) insect/leaf increase for insecticides (Mitrixin, Levo, Evisect) respectively. In a field study, the effect of insecticide toxicity for nymphs and adults of *C. rusci* L. (Coccidae: Hemiptera) was tested. The Results showed that the insecticides Mitrixin distinct in the after two weeks treatment and levo insecticide in after a day treatment and after two weeks treatment while the lethal rate is (64.32, 63.49, 58.73) insect/leaf in (Matrixin, Levo, Evisect), respectively.

Keywords: Actara Ceroplasts rusci, Insecticides, Mitrixin,Nymph, Polo.

1. Introduction

The fig wax scale *C. rusci* L. (Coccidae: Hemiptera) is the most important pest on fig trees in orchards, spread throughout the Mediterranean, Greece, and the Arab world. It is found in Iraq, Palestine, Syria, Lebanon, Egypt, and Libya. Tunisia. In particular, the figs infest other plant families such as the green bean in Turkey, 2004: Ulgenturk and Canakcio,2003: Qin, and Gullan, 1995) as well as pistachios and ornamental plants. This insect spends the winter season as a nymph in the second stage. Rarely, in the adult insect stage in the area around Beirut, many die when leaves fall, as the autumn heat increases, the second stage nymphs begin to feed, grow and molting the Cuticle at the beginning of March until they become adults (Qin and Gullan, 1995; Al-Hariri,1980). White females are placed after 8-15 days. In the middle of May, the nymphs creep under the cortex of the mother, roaming the leaves, and fruits for 3-8 days until finding a suitable place to stick to it and begin to feed and settle on the middle veins, and other veins and fruits(Al-Mallah, et al, 2017: Abu- Huiege,1962). The weakening of fig trees because of the feeding of this lesion expose them to the injury of stray fossils, the role of the formation of this insect is an important source of the transfer of the pest from one orchard to another through the transfer of infested seedlings for propagation (Al-Mallah, and NABIL,2017: Abu- Huiege,1962), there is no study of the extent of the damage in Iraq as well as the difficulty of combating traditional insecticides imported by the Food and Agriculture Organization International (FAO), as many failed attempts to control this lesion in many locations of Iraq, which this study to evaluate the efficiency of some biocides and systemic access to Which results in the possibility of applying the Integrated combat to control of this key Pest on figs in the orchards of Iraq.

2. Materials and Methods of Work

1 - Study Location:

The study was carried out in 2017. Laboratory studies were carried out in the graduate laboratory of the Plant Protection Department at the Faculty of Agriculture / University of Tikrit under laboratory conditions.

Field trials were carried out in the fig orchards located in the Balad area, 90 km from Saladin Governorate. And about 50 km north of Baghdad has not been controlled by any insecticide or chemical and the age of trees in orchards ten years. Fifteen trees
were selected randomly for study by three trees for treatment (treatments + treatment comparison). The results were analyzed according to the complete random design method (CRD) and the least important difference (L.S.D) was used to confirm the importance of the differences between the different transaction rates below 0.05 to compare the results.

2.1. Experimentation of the Division of Some Biodicides and Systemic In the Percentage of Deaths in Nymphs and Adults of C. Ruscii L.

The efficiency tests of the insecticides mentioned above were carried out according to the concentrations mentioned in Table (1) where the recommended concentration was adopted, the lowest and the highest concentration to determine the best concentration in which the insecticide gives the highest percentage of kills. The laboratory experiment was carried out as the infested leaves were taken from trees and counting the number of nymphs and live adults before the control. The insecticide solution was sprayed on the infected leaves with dilute solution concentrations of the tested insecticides and by three replicates of the treatment. The nymphs and adult insects were followed by the first moving gently with a small brush, and then the dead were examined with a needle. The number of changed from the leaf easily and became black or brown. The models were taken 24 hours before the control or after three days of control, and the Henderson, Tilton equation was used to find the percentage of efficacy of each insecticide in the control of the insect (Al- Mallah and AL- Jabure, 2014).

\[
\text{Percentage of toxicity} = \left(1 - \frac{N_1 + \frac{X_2}{2}}{N_2 \times X_2}\right) \times 100
\]

whereas:
N1: Number of treated insects after spraying
N2: Number of treated insects before spraying
X3: Number of insect deaths after spraying
X4: Number of insect deaths before spraying
Data were recorded in a special book that was statistically analyzed using Excel and SAS software (Al-Samarrai, 2009).

- The Evaluation's experiment of some biochemical and systemic insecticides in the percentage mortality of nymphs and fig leaf insects. The efficiency of the tested insecticides was tested in the field using the recommended concentration during the period of the suspension of movement and the process of multiplication of the adult insect. The single replicator adopted one infested leaf of 5 leaves for each randomly selected tree. The trees and leaves were numbered, and the treatment was randomly selected in the selected trees. The data was recorded in a special record was taken first reading of the animals of the nymphs and adults insects 30/9/2017 and then sprayed with insecticides by a hand-made 2-litter tray Chinese-made, and on After day took readings of the nymphs and adults After two days and After one week, and After two weeks Percentages were extracted To kill according to the Henderson equation and then extract the corrected homicide ratio using the Abbott equation (Abbott, 1925).

3. Results & Discussion

First: Determine the relative effectiveness of insecticides used: The results of the toxicity line diagram in Figure (1) showed that the Mitrixin insecticide affected the Mortality percentages of the nymphs and adults of the fig wax scale, noting that the corrected percentage of mortality increases with the increased of concentration used when treating nymphs and adults. The ratio was 22.003 insect/ml (minimum concentration) and increased with increased concentration to reach a corrected percentage of 59,283 insect/leaf mortality in the 0.6 ml/L concentration treatment (maximum concentration). Notice from Figure (1). Through the Toxicity line, LC50 (lethal dose value for half of the test objects) or LD50 (Al- Mallah and AL- Jabure, 2014) can be identified from the toxicity line equation:

\[
Y = 186.4X - 57.968
\]

Y represents the value of sensitive individuals, and X represents the concentration. The LC50 value was 0.58 mm / L and from Fig. 2, 3, and through the toxicity line, the Levo and Asset isolates affected the corrected Mortality percentage of the nymphs and adults. The Mortality percentages increased with the highest corrected rate of 53.943, 52.247 insect/leaf In the concentration of 0.4, 1.1 mm/L respectively (the highest maximum concentration) and the toxicity line equation for both insecticides, the value of LC50 is 0.397, 1.1 mm / L respectively, and in Fig. 4. The percentage of mortality of nymphs, and adults from the rest of the insecticides was LC50 for them 0.55, 0.6 mm /L respectively, and these results agree with what he said (Ragab, 1995).

Figure (2) The toxicity line of concentrations of Levo and the rates of %mortality. When the insecticide was used directly as the intensity of the fig leaf decreased, but the results were not at the required level. First: Determine the relative effectiveness of insecticides used: The results of
the toxicity line diagram in Figure (1) showed that the Mitrixin insecticide affected the Mortality percentages of the nymphs and adults of the fig wax scale, noting that the corrected percentage of mortality increases with the increased of concentration used when treating nymphs and adults. The ratio was 22.003 insect mL/L (minimum concentration) and increased with increased concentration to reach a corrected percentage of 59.283 insect/leaf mortality in the 0.6 mL/L concentration treatment (maximum concentration).

Notice from Figure (1). Through the Toxicity line, LC50 (lethal dose value for half of the test objects) or LD50 (Al- Mallah and AL- Jabure, 2014) can be identified from the toxicity line equation:
\[ Y = 186.4X - 57.968 \]

Table (3) shows that the average percentage of the effectiveness of the insecticides used in the study increased with increased concentration. The matrixin gave the highest relative efficacy in the nymphs and adults of the fig leaf at the concentration of 0.6 mm/l and reached 59.283 insect/leaf followed by the insecticide Levo and Evisect at 53.943 and 52.247, respectively, while the relative efficacy of the polo and acetra decreased by 37.827 33,638 insect/leaf and The decrease in toxicity was due to the nature of the effect of the insecticides and did not affect contact with the presence of the wax layer (Al-Mallah and NABIL, 2017).

Table (4) shows that there is a difference in the average Mortality percentages for nymphs and adults of the fig leaf according to the type of insecticide used and the intervals of the field Mortality percentages, as the insecticide exceeded the matrix and gave the highest effect in the last reading after two weeks for the remaining insecticides. Which gave the highest effect in the percentage of Mortality percentages of nymphs and insects after two weeks after two weeks reaching 64.32 insect/leaf, the results of the statistical analysis showed that there was no significant difference between the previous treatments and the treatments of the Levo after two weeks and after day, with the highest result of this insecticide in all readings, reaching 63.49. 61.45 insect/ leaf respectively.

In the same table, it is noted that the values of mortality increased according to the increase in the period of exposure of the insecticide, as the last readings gave the highest rates of overlap of the type of insecticide and the statistical analysis noted that the highest rate of mortality was in the last readings of the total insecticides as in the reading after two weeks the rate of mortality 58.61 insect/leaf and polo were eliminated at the same time as 56.4 insects/leaves. The Mortality percentage in the first readings of insecticides dropped to 16.99-14.85 ppm/sheet for the polo and Levo insecticides respectively.

4. Conclusions

The study concluded that:

1-Livo can be used at a concentration of 0.3% during the activity of the insect. This concentration can reduce the insect density to more than 50%.

2-The Matrixin insecticide has succeeded in reducing the density of the pest to more than 60%.

3-Actara recommends to use as an insecticide in the control of the insect at the time of tree growth has succeeded in reducing the numerical density of the pest by more than 50%, preferably in the integrated pest management (IPM) of the sub-lethal concentration with other control operations.
