Abstract

This work reports effect of the powder grain size distributions on the bending strength sintered Ni-30%Fe alloys obtained from mixed coarse-fine micron size metal powders. Two dissimilar particle sizes of Ni and Fe metal powders were mixed by subjecting them to translational and rotational agitations using the T2F Turbula Shaker Mixer. The mixed powders were moulded using graphite dies and sintered in vacuum and at constant pressure using Spark Plasma Sintering furnace (HPHD-25). The ratios of the two metals were varied as well as the sintering temperature and time. The morphology and microstructures of both powders and sinters were studied using field emission scanning electron microscopy (JSM-7600F) equipped with energy dispersive X-ray spectrometer (EDS) facilities. The phases in the sintered specimens were characterized by X-ray diffraction (XRD). The densities of the samples were determined, The Vickers microhardness at room temperature and bending strength of the sintered alloy specimens were measured. Comparatively, low heating rate (50 °C/min) produced enhanced microstructures hence higher bonding, bending strength and densification than samples at high heating rate (150 °C/min).

Keywords: Sintering; Grains; Bending Strength; Particle Size.

1. Introduction

The use of advanced materials in different areas of modern technology has led to enhancement in the function, quality and performance of engineering parts and systems [1]. Nickel-base alloys are unique with combinations of properties making them useful in diverse dedicated applications. The soft magnetic properties of Ni-Fe alloys are used in electronic, electromagnets and communication equipments. Ni-Fe alloys have low expansion characteristics due to balance between thermal expansion and magnetic property changes with temperature. Also Ni-Fe alloys are useful in storage and transportation tanks for liquid natural gas industry; transducers (45-50Ni-Fe), magnetic amplifiers (oriented 49Ni-Fe), sensitive direct current relays (45-49Ni-Fe), temperature compensator (29-36 Ni-Fe), shielding (49Ni-Fe), dry reed magnetic switches DRMS (51Ni-Fe), chart recorder (instrument) and synchronous motors (49Ni-Fe).

Some other properties of significance that enlarge the usefulness of Ni alloys include: the shape memory characteristics of nickel alloys, the high strength at elevated temperatures, and the resistance to stress relaxation. Soft magnetic Ni-Fe alloys consisting about 30 to 80% Ni are used extensively for their high saturation magnetization and constant permeability with changing temperature. For high expectation of ductility and malleability, Ni-Fe alloys are usually made as strip or sheet product; though, billet, bar, and wire can be produced as required [2].

Production of cast Ni-Fe from melt can be difficult due to the chemical reactivity of the melt that frequently results in segregation defects [3]. Powder metallurgy (PM) methods to formulate Ni-SMA were affected by the complications faced with usual methods. PM is a practice that lessens the problems related to liquid metal casting, permits a precise composition management and the capability to manufacture a range of components shapes. Therefore, conventional sintering is seen as a viable method of making porous Ni SMA [4]. However, dense materials are not easy to attain, mostly when starting with elemental powder [5]. Sintering process can be realized in the two-stage regime; involving the preliminary sintering of P/M compacts in solid phase and the final sintering with liquid phase executed in vacuum [6].

Sinter-hardening technique SHT presents another way of hardening metal powder components beside the traditional austenitization, quenching, and tempering routines. SHT has numerous advantages such as the reduced number of manufacturing procedures and averting part contamination with oil. SHT can be accomplished in different ways as using sintering furnaces with customized ferrous PM alloy admixture systems and using dedicated PM alloys in combination with furnaces having fast cooling zones. SHT compact the PM component, sinter, and temper in a cycle with optimization of each step to guarantee consistent making of sinter-hardened parts [7].

Though, there are reports on the binary alloys of Nickel with iron group elements. The gap still exists in relating and understanding the roles of diversities in powder metal grain sizes as regarding the densification and sintering parameters on the enhancing superior mechanical (bending strength) and magnetic characteristics (microstructure) of Ni-Fe alloy in particular [8-11]. There is still great necessity to investigate the Ni-Fe alloy systems more intensely. Hence this work studied the influence of grain particle size distribution and sintering parameters (Heating rate (°C/min), reference temperature (°C) and dwell time (min)) on the bending strength of the sintered Ni-30%Fe alloys produced from the mixture of...
coarse-fine micron sized powders. It reflects the aspect of the larger scope partly reported in the previous literatures [10-12].

2. Experimental procedures

2.1. Material preparation

Two different particle sizes of elemental Ni and Fe powders with compositions summarized in Table 1 were selected as starting materials. A 250 ml cylindrical plastic vessel with a powder fill level of 10% was loaded axially, placed in the mixing chamber and subjected to combined translational and rotational agitation. The coarse and fine sizes of Ni and Fe powders were dry mixed using the Turbula Shaking Mixer T2F at speed of 49 rpm and time of 5h. The morphology of the as received and blended powders were then examined with a field emission scanning electron microscopy (FESEM, JSM-7600F, Jeol, Japan) equipped with energy dispersive X-ray spectrometer (EDS) facilities.

2.2. Sintering procedure

The mixed powders were packed in 30 mm inner-diameter graphite dies, lagged with 0.2 mm thick graphite foils; and sintered by SPS (HHPD-25, FCT GmbH Germany). The graphite foils afford easy removal of the sinter and significant reduction of temperature inhomogeneities. In addition, the die exterior was covered with -10 mm thick porous graphite felt, used as a thermal insulation to reduce the radiation loss and possible temperature gradient [8-9]. Sintering was done in vacuum and at constant pressure of 30 MPa. In all cases, heating schedules were controlled by a preset heating program as shown in Table 2. At the end of the heating regime (temperature and time); the electric current was shut off, the applied stress released, and the specimens were furnace cooled. The temperature was measured by an optical pyrometer implanted at 3 mm from the top of the sample surface in the SPS apparatus. Sinter discs of approximately 30 mm diameter by 5 mm high were produced.

2.3. Density and microstructural characterization

The sintered specimens’ surfaces were ground and polished to remove any graphite contamination. The densities of the specimens were determined using Archimedes principle. The relative density (%) was calculated with reference to the theoretical density of the starting powders constituents using the rule of mixtures. The microstructures of the specimens were examined from the polished surface at cross sections (parallel to the acting force) of the sintered bodies: using field emission scanning electron microscope (FESEM, JSM-7600F, Jeol, Japan) with an EDX detector (Oxford X-Max) with an INCA X-Stream 2 pulse analyzer software, and back scattered electron detectors. The INCA analyzer software was set to 70 s and 2 s of acquisition and process time respectively. The polished specimens were chemically etched with a 6% nitric acid solution for 15 seconds to observe the microstructure and measure the grain size. Focus was given to studying the microstructure at different regions along the cross section. Only the cross section of the specimen was examined to avoid the near-surface effects and some other uncertain factors. The phases present in the sintered specimen were characterized by X-ray diffraction (XRD) using a PANalytical Empyrean model with Cu Kα radiation and Highscore plus software. The XRD analysis was carried out on the section perpendicular to uniaxial pressed direction.

2.4. Mechanical property measurement

The Vickers micro hardness (HV₁) at room temperature was measured by a Vickers’ micro hardness tester (Future-tech) at a load of 1.0 kg and dwell time of 10s. The test result for each sample was the arithmetic mean of ten successive indentations with standard deviations. A Tinius Olsen system (London) measured the bending strength of the sintered alloys, of specimens of 16.00 × 5.00 × 2.00 mm³ with a loading rate of 0.05 mm/min. The bending strength σₚₚ is calculated from (1):

\[
\sigma_{bb} = \frac{3FL}{2bh^2}
\]

Where \(\sigma_{bb}\) is the bending strength, \(F\) is applied force, \(L\) is length, \(b\) is breadth and \(h\) is the thickness of the sample respectfully.

3. Results and Discussions

The mixed powders are of round, non-porous and spherical shapes as illustrated in Figure 1(a). The SEM micrographs of the Ni-30%Fe alloy shows the microstructural evolution of the samples with different starting particle size: (a) 3 µm FeNi and (b) 70 µm FeNi, where 1 and 2 respectively represent 50°C/min and 150°C/min heating rates are presented in Fig. 2. In all cases the sintered specimens produced (a.1, b.1, a.2 & b.2) in Fig 2 are porous, with fractures (cracks) both on the surface (matrix) as well as at the grain boundaries.

Fig. 1: The Mixed Powder Grains of (A) Ni (70, 0.3 µm) and (B) Fe (44, 3 µm).
deformed within the heating regime. Comparable microstructures were seen in all specimens that show signs of serrated flow [10-11].

Fig. 3 shows the SEM micrographs of the SPS sintered Ni-30 % Fe alloy. It shows the fractured surface of the samples with different (a) 3µm-FeNi and (b) 70µm-FeNi starting particle sizes; operated at 50°C/min and 150 °C/min heating rates. Fig 3a.1 shows that SPS produced high level of fusion of the particle with sponge like nature of the sinter at the working heating rate. Fig 3a.2 shows crack characterized surfaces on the particles. There was high degree of tendency of the diffusion of the smaller or fine particles melting out on the surfaces and at boundaries thereby initiating bonding of the coarse particles. Comparatively, slow heating rates (a.1 and b.1) produced enhanced microstructures hence higher bonding, bending strength and densities than a.2 and b.2 as obtained in Figs 4 and 5.

The effect of particle sizes of Ni (70, 0.3 µm) and Fe (44, 3 µm); and the heating rates (50°C/min and 150 °C/min) on bending strengths of Ni-30%Fe sinters reduced with the heating rates from 50 to 150 °C/min. The 3 µm NiFe (1) alloy has highest bending strength of about 750 MPa and densification of 98.8%. The results in Figure 4 and 5 matched with the observation in Figure 3.

The sinters produced could be classified as γ-strengthened (Ni-rich) Ni-Fe based family. With high Ni content (> 40% Ni) in the alloy i.e γ-strengthened, higher volume fraction (Vf) of γ results in better high temperature properties; and such NiFe alloy may be used in structural applications. It is obvious that these alloys are very susceptible to processing and heating regimes. As obtained in the present work (Fig. 1-5), the real phases that are noticed in the finished products are appreciably influenced by heating rate and variations in particle sizes of the mixed NiFe metal powder.

4. Conclusion

The effects of grain distribution and heating rate on bending strength of mixed coarse-fine sized sintered Ni-30%Fe Alloys have been studied and from the results obtained, the following conclusions are made: The morphology and the microstructures of the powders and sinters showed that the mixed powders are of round, non-porous and spherical shapes. The microstructural evolution of the samples with different starting particle size: (a) 3 µm-FeNi and (b) 70 µm-FeNi, sintered at 50 °C/min and 150 °C/min heating rates revealed that in all cases, the sintered specimens produced (a.1, b.1, a.2 & b.2) are porous, with fractures (cracks) both on the surface (matrix) as well as at the grain boundaries. The SEM imagery showed that specimens deformed within the heating regime. Comparable microstructures were seen in all specimens that show signs of serrated flow. It also shows that SPS produced high level of fusion of the particle with sponge like nature of the sinter at the working heating rate. Comparatively, slow
heating rates (a.1 & b.1) produced enhanced microstructures hence higher bonding, bending strength and densities than a.2 & b.2
